Abstract: Adolescents view thousands of food commercials annually, but the neural response to food advertising and its association with obesity is largely unknown. The current study is the first to examine how neural response to food commercials differs from other stimuli (e.g., non-food commercials, television show) and to explore how this response may differ by weight status. The blood oxygen level-dependent functional magnetic resonance imaging activation was measured in thirty adolescents ranging from lean to obese in response to food and non-food commercials imbedded in a television show. Adolescents exhibited greater activation in regions implicated in visual processing (e.g., occipital gyrus), attention (e.g., parietal lobes), cognition (e.g., temporal gyrus, posterior cerebellar lobe), movement (e.g., anterior cerebellar cortex), somatosensory response (e.g., postcentral gyrus), and reward (e.g., orbitofrontal cortex, anterior cingulate cortex (ACC)) during food commercials. Obese participants exhibited less activation during food relative to non-food commercials in neural regions implicated in visual processing (e.g., cuneus), attention (e.g., posterior cerebellar lobe), reward (e.g., ventromedial prefrontal cortex, ACC) and salience detection (e.g., precuneus). Obese participants did exhibit greater activation in a region implicated in semantic control (e.g., medial temporal gyrus). These findings may inform current policy debates regarding the impact of food advertising to minors.

Keywords: marketing, adolescents, obesity, fMRI

1. Introduction

Individuals are exposed to a vast amount of food advertising, particularly adolescents, who are frequently targeted as a key advertising demographic (Federal Trade Commission, 2012). The average adolescent was exposed to approximately 6,000 television food advertisements in 2010 (Rudd Center for Food Policy and Obesity, 2011), with most commercials promoting products high in calories, sugar, sodium and/or fat (Powell, Schermbeck, Szczypka, Chaloupka, & Braunschweig, 2011). Yet, little is known about how the brain responds to these advertisements, which may be of importance for individuals at-risk for obesity. Individual differences in the response to food advertisements may contribute to problematic food consumption, but the food images used in prior studies of obesity differ in meaningful ways from food commercials. Thus, our understanding of how food advertisements impact brain reward and attention regions is limited, as is our knowledge of how this may differ based on body mass. This study was designed to address these two questions.

Meso-limbic-cortico regions (e.g., ventral striatum, insula) appear to encode the reward value of food images and cues (Stoeckel et al., 2008; Van der Laan et al., 2011) and obese relative to lean participants have been found to show greater neural activation in brain regions implicated in reward (e.g., orbitofrontal cortex [OFC]), visual attention (e.g., parietal lobe), memory (e.g., hippocampus), cognition (e.g., temporal lobe), and somatosensory processing (e.g., postcentral gyrus) in response to food cues (Bruce et al., 2010; Carnell & Wardle, 2007; Martin et al., 2009; Rothemund et al., 2007; Stice, Yokum, Bohon, Marti, & Smolen, 2010; Stoeckel et al., 2008). Elevated nucleus accumbens response to high-fat/sugar food images (Demos, Heatherton, & Kelley, 2012) and OFC response to cues signaling impending unhealthy food image presentation predicted future weight gain (Yokum, Ng, & Stice, 2012). Further, activation in reward, visual and attention areas (e.g., insula, OFC, parietal and occipital lobe) during exposure to food cues is associated with less successful weight loss and increased weight regain (Murdaugh, Cox, Cook Iii, & Weller, 2012).

Although these results highlight the potential role of food-cue responsivity in obesity, the stimuli used in these studies are typically a picture of food without branding and without context, limiting ecological validity.

Thus, these findings provide limited information about how food advertisements in the current environment may contribute to problematic eating. In contrast to food pictures used in prior studies, food commercials are specifically designed to induce the desire to consume the advertised product (Council of American Research Survey Organizations 2005). Not only do food commercials present enticing images of unhealthy and highly palatable foods, but successful advertising also creates positive associations with brands and reinforces them every time an advertisement is viewed (Heath, 2001). Brands associated with basic human motivations (e.g., happiness, attractiveness, accomplishment) encourage product sales (Wansink, 2003) and food advertising to young people typically utilizes appeals to these attributes (Schor & Ford, 2007). Consumption of a preferred brand (e.g., Coca-Cola) is related to increased activation in the hippocampus, dlPFC, and midbrain (McClure et al., 2004). Further, healthy-weight children have shown greater activation in the OFC, temporal cortex and visual cortex during exposure to food logos (e.g., McDonald's arches) relative to control images (Bruce, Bruce, et al., 2012); exposure to food logos relative to non-food logos were also related to greater activation in the occipital cortex, paracentral lobule, parietal gyrus, lingual gyrus, and posterior cingulate cortex. Further, obese relative to lean children exhibit greater activation in somatosensory and reward-related regions (i.e., postcentral gyrus, midbrain) for food logos compared to control images (Bruce, Lepping, et al., 2012).

Thus, participants may respond more strongly to food commercials (which contain branded food images) relative to non-food commercials or a television show. The current study is the first to examine the neural correlates of food commercials relative to control stimuli. The major aims of this study are 1) to examine whether food commercials relative to non-food commercials and television viewing are related to differential patterns of activation in brain regions implicated in visual attention, somatosensory response, reward and motivation (e.g., OFC, postcentral gyrus, occipital lobe) and 2) to evaluate whether neural response to these stimuli differ by weight class (e.g., obesity vs. normal weight). Although a number of strategies to choose commercial stimuli were considered for this study (e.g., matching food and non-food commercials on visual characteristics, price, participant preferences, etc.), we focused on real-world exposure by choosing

commercials based on data from Nielsen on television and advertising exposure for 12- to 17-year olds. To further increase the generalizability of our paradigm to settings where food commercials are typically encountered, commercials breaks were embedded in the context of a television show. Finally, we conduct the current study in adolescent participants, as this is a target demographic for food advertisements (Federal Trade Commission, 2012) and a risk period for the development of obesity (Ogden, Carroll, Kit, & Flegal, 2012).

2. Material and methods

2.1 Participants

Participants were 30 healthy adolescents (M age = 15.20, SD = 1.06, $Range$ = 14-17 years old; M BMI = 26.92, SD = 5.43; 17 females) recruited from the community via ads. To examine how neural response to food commercials differs by weight class, we enrolled a roughly equivalent number of participants in each weight category: 10 normal weight (M BMI = 21.20, SD = 0.90), 8 overweight (M BMI = 25.53, SD = 1.41), and 12 obese (M BMI = 32.64, SD = 5.43). Exclusion criteria were current regular use of psychotropic medication or illicit drugs, pregnancy, head injury with a loss of consciousness, or current Axis I psychiatric disorder. In total, 6.7% reported being Hispanic, 63.3% European Americans, 3.3% Native Americans, and 26.7% mixed race/ethnicity. There were no significant differences in age ($F_{2,27} = 3.12, p = 0.06$), or parental education level ($F_{2,27} = .157, p = 0.85$) for obese, overweight, and lean participants. The local Institutional Review Board approved this project. Participants and parents provided written informed consent.

2.2 fMRI Media Paradigm

Participants were asked to consume a typical breakfast/lunch, but to refrain from eating or drinking (except water) 5 hours immediately preceding their scan in an effort to standardize hunger. To motivate participants to attend to the clips, participants were told they would complete a commercial-recognition task after the scan. Prior to scanning, participants rated hunger levels on a visual analog scale (*not hungry at all* to

never been more hungry). Hunger was included as a control variable in all analyses. All participants were scanned in the afternoon (M time onset scan = 4PM, $SD = 1.5$, range = 1PM-6PM).¹

Data were obtained from Nielsen to measure the number of television ads viewed by 12- to 17-year old individuals in 2009 for all food brands. After eliminating brands that are clearly aimed at younger children (e.g., Chuck 'E Cheese), the ten food brands advertised most frequently to this age group were identified. Commercials for these ten brands were chosen as food commercial stimuli. For non-food commercial stimuli, Nielsen data were used to identify the weekly television programs that appeared during the first quarter of 2009 with the largest audience of 12- to 17-year olds (“American Idol,” “Family Guy,” “Simpsons,” “George Lopez,” and “Secret Life of the American Teenager”). During January 2010, each of these programs, including the commercials, was recorded twice. Commercials for the ten most frequently featured non-food brands were selected for inclusion as study stimuli (see Table 1).

During scanning, participants saw a video of the television show “Mythbusters” that was edited to include 20 food commercials and 20 non-food commercials (two commercials from each brand, see Table 1). The commercials were shown over 4 breaks (10 commercials per break, 15 seconds per commercial). This number of commercials in the paradigm was chosen to provide an adequate number of opportunities to capture blood oxygenation level-dependent (BOLD) activation during the commercials. Order of the commercials was randomized over the four breaks and the order of the four breaks was randomized over the participants. The duration of each break was 2 minutes and 30 seconds. Total paradigm duration was 34 minutes.

2.3 Measures

2.3.1 Body Mass Index (BMI). The body mass index ($BMI = \text{kg}/\text{m}^2$) was used to reflect adiposity. To compute BMI, height was measured to the nearest millimeter and weight was assessed to the nearest 0.1 kg (after removal of shoes and coats). Obesity was defined using the 95th percentiles of BMI for age and sex, based on historical nationally representative data because this definition corresponds closely to the BMI cut-point that

¹ All main effects remained significant when time of day that scanning occurred was controlled for in analyses.

is associated with increased risk for weight-related health problems (Cole, Bellizzi, Flegal, & Dietz, 2000). Adolescents with BMI scores between the 25th and 75th percentile using these historical norms were defined as lean and adolescents with a BMI score between the 75th and 95th percentile were defined as overweight.

2.3.2 Pubertal development. Adolescents were asked to report on their current state of pubertal development using a standardized series of line drawings of youth at various states of pubertal development (Bonat, Pathomvanich, Keil, Field, & Yanovski, 2002).

2.3.3 Commercial recall measures. Participants were asked to list five commercials that they had seen during the television program they just viewed to measure top-of-mind recall. Additionally, participants were given a list of 40 different products, including products that were and were not included in the television program, and asked to indicate whether they had seen commercials for these products to assess aided recall.

2.3.4 Commercial liking and familiarity measures. Participants were asked to rate how much they liked the products/companies featured in the advertisements on a 5-point likert scale (*dislike extremely* to *like extremely*) and how familiar they were with the advertisements on a 5-point Likert scale (*not at all familiar* to *extremely familiar*).

2.4 Statistical analyses

2.4.1 fMRI data acquisition, preprocessing, and statistical analysis. Scanning was performed with a Siemens Allegra 3 Tesla head-only MRI scanner using a standard birdcage coil. Functional scans used a T2* weighted gradient single-shot echo planar imaging (EPI) sequence (TE = 30ms, TR = 2000ms, flip angle=80°) with an in plane resolution of 3.0 x 3.0 mm² (64 x 64 matrix; 192 x 192 mm² field of view). To cover the whole brain, 32 interleaved, no skip, 4mm slices were acquired along the AC-PC transverse oblique plane, as determined by the midsagittal section. Prospective acquisition correction (PACE) was applied to adjust slice position and orientation, as well as to re-grid residual volume-to-volume motion in real-time during data acquisition for the purpose of reducing motion-induced effects (Thesen, Heid, Mueller, & Schad, 2000). No participant's data set failed to meet the movement inclusion criteria, which were that within-run movement

before correction did not exceed 2 mm in translational movement and 2^0 in rotational movement. For smaller movements, PACE adjusts slice position, orientation and regrids the residual volume-to-volume motion during data acquisition. Anatomical scans were acquired using a high-resolution inversion recovery T1 weighted sequence (MP-RAGE; FOV = 256 x 256 mm², 256 x 256 matrix, thickness = 1.0 mm, slice number \approx 160).

Images were manually reoriented to the AC-PC line and skull stripped using the BET function in FSL (Smith, 2002). Data were pre-processed and analyzed using SPM8 (Wellcome Department of Imaging Neuroscience) in MATLAB (Mathworks Inc.; Worsley et al., 1996). Functional images were realigned to the mean and both the anatomical and functional images were normalized to the standard Montreal Neurological Institute (MNI) T1 template brain (ICBM152). Normalization resulted in a voxel size of 3 mm³ for functional images and a voxel size of 1 mm³ for high-resolution anatomical images. Functional images were smoothed with a 6 mm FWHM isotropic Gaussian kernel.

We contrasted BOLD activation during food commercials versus non-food commercials, food commercials versus a television show, and non-food commercials versus a television show. Because there were 20 food commercials and 20 non-food commercials, we also included 20 randomly selected segments of the television show. Condition-specific effects at each voxel were estimated using general linear models. Vectors of the onsets for each event of interest were compiled and entered into the design matrix so that event-related responses could be modeled by the canonical hemodynamic response function, as implemented in SPM8. The event consisted of the entirety of the 15-second commercial and television segment. A 128 second high-pass filter was used to remove low-frequency noise and slow drifts in the signal.

Individual maps were constructed to compare the activations within each participant for food commercials, non-food commercials and television show. Consistent effects across subjects were then tested using the contrast images in one-sample t-tests (conforming a Random Effects model). We then created three groups based on weight status (obese, overweight, and lean) and conducted second-level 3 (Group: obese, overweight, lean) x 2 (stimulus type: food commercials, non-food commercials, television show) random-

effects analysis of variance (ANOVA). As this study uses a novel paradigm (i.e., commercials imbedded in the context of a television show), whole-brain analyses were conducted throughout to allow for the identification of peaks in brain regions outside the classic reward regions (e.g., visual processing, attention) that may play a role advertising response. Cluster level thresholds corrected for multiple comparisons were derived using a Monte Carlo simulations (10,000 iterations) of random noise distribution in the whole brain mask (3x3x3mm) using the 3dClustSim and 3dFWHMx modules in AFNI (Cox, 1996; Forman et al., 1995). Using intrinsic smoothness, the Monte Carlo simulation combines individual voxel probability threshold and minimum cluster size to estimate the probability of a false positive. The threshold resulted in $p < 0.001$ with a cluster (k) ≥ 19 , which is equal to $p < 0.05$ corrected for multiple comparisons across the whole brain. All contrasts were run in both directions (e.g., food commercials $>$ non-food commercials and non-food commercials $>$ food commercials) and only significant peaks are reported. Effect sizes (r) were derived from the Z-values (Z/\sqrt{N}).

3. Results

3.1 Behavioral Results

Overall, participants recalled more food ($M = 2.69$, $SD = 0.92$) than non-food commercials ($M = 2.0$, $SD = 0.88$; $t(29) = 2.25$, $p = 0.03$) and recognized more food commercials ($M = 1.78$, $SD = 0.32$) than non-food commercials ($M = 1.60$, $SD = 0.33$; $t(29) = 3.13$, $p = 0.004$). Participants reported liking the food commercials better ($M = 3.52$, $SD = 0.49$) than non-food commercials ($M = 3.24$, $SD = 0.36$; $t(29) = 2.29$, $p = 0.03$) and reported to be more familiar with food ($M = 4.08$, $SD = 0.75$) than non-food commercials ($M = 3.72$, $SD = 0.99$; $t(29) = 3.13$, $p = 0.004$). Hunger ratings suggest that participants were on average in a neutral hunger state (M hunger = 0.63, $SD = 3.69$) prior to their scan session.

There were no significant differences between obese, overweight, and lean individuals on pubertal development ($F_{(2,27)} = 1.44$, $p = 0.26$), hunger ratings ($F_{(2,27)} = 1.58$, $p = 0.22$), aided recall of food commercials ($F_{(2,27)} = 0.07$, $p = 0.94$), aided recall of non-food commercials ($F_{(2,27)} = 0.06$, $p = 0.95$), top-of-mind recall of food commercials ($F_{(2,27)} = 0.08$, $p = 0.92$), top-of-mind recall of non-food commercials ($F_{(2,27)} = 0.17$, $p =$

0.85), liking ratings of non-food commercials ($F_{(2,27)} = 0.40, p = 0.67$), familiarity of food commercials ($F_{(2,27)} = 0.29, p = 0.75$), and familiarity of non-food commercials ($F_{(2,27)} = 0.29, p = 0.76$) (Table 2). However, there was a significant difference among the three groups in liking ratings of the food commercials ($F_{(2,27)} = 4.57, p = 0.03$). *Post-hoc* tests showed that obese participants ($M = 3.26, SD = 0.43$) reported lower liking ratings of food commercials than overweight participants ($M = 3.83, SD = 0.33$).

3.2 Main Neural Responses to Food Commercials Compared to Non-Food Commercials

On average participants exhibited greater activation in bilateral posterior cerebellar lobe (declive) (r left > 0.9 and r right > 0.9; Fig 1A), bilateral middle occipital gyrus (MOG; r left > 0.9 and r right = 0.87), right precentral gyrus ($r > 0.9$), right inferior temporal gyrus (ITG; $r > 0.9$), bilateral inferior parietal lobe (IPL; r left = 0.88 and r right = 0.75), left postcentral gyrus ($r = 0.78$), right precuneus ($r = 0.74$), and right superior parietal lobe (SPL; $r = 0.69$) (Table 3). The areas of greater neural response for non-food commercials and the television show are included in the supplementary materials (Supplementary Table 1).

3.3 Main Neural Responses to Food Commercials Compared to Television Show

Participants exhibited greater activation in the left cuneus ($r > 0.9$), bilateral posterior cerebellar lobe (r left > 0.9 and r right > 0.9), right anterior cerebellar lobe (culmen) ($r > 0.9$), right lingual gyrus ($r > 0.9$), bilateral MOG (r right > 0.9 and r left = 0.74), left cingulate gyrus ($r = 0.85$), right ventromedial prefrontal cortex (vmPFC; $r = 0.72$; Fig1B), left anterior cingulate cortex (ACC; $r = 0.71$), and right ventromedialPFC/medial OFC (vmPFC/medial OFC; $r = 0.68$).

3.4 Relation between Main Neural Responses and Self-Report Ratings of Commercials

Because participants recalled more food commercials than non-food commercials, reported greater familiarity with food versus non-food commercials, and reported greater liking of food commercials versus non-food commercials, we examined the relations between these variables and the main neural responses. We extracted the main effect parameter estimates at the individual level and calculated the Pearson correlation coefficients in SPSS (SPSS for Windows, version 19.0, IBM-SPSS, Chicago, IL). Activation in the left

posterior cerebellar lobe in response to food commercials relative to non-food commercials was positively correlated with familiarity ratings of food commercials ($r = 0.46, p = 0.03$). Activation in the mid cingulate cortex in response to non-food commercials relative to food commercials was negatively correlated with liking ratings of non-food commercials ($r = -0.49, p = 0.02$). There were no significant correlations between the main neural responses and recall measures.

3.5 Differences in Brain Activation in Response to Food Commercials versus Non-Food Commercials between Obese, Overweight, and Lean Individuals

Obese individuals showed greater activation in the middle temporal gyrus (MTG; $r = 0.77$) and less activation in the left cuneus ($r = -0.74$; Fig 2A) and left posterior cerebellar lobe ($r = 0.70$) compared to overweight individuals (Table 4). Overweight individuals showed greater activation in the left cuneus ($r = 0.73$) and left posterior cerebellar lobe ($r = 0.73$) compared to lean individuals (Table 4).

3.6 Differences in Brain Activation in Response to Food Commercials versus Television Show between Obese, Overweight, and Lean Individuals

Obese individuals showed greater activation in the MTG ($r = 0.74$) compared to overweight individuals and less activation in the vmPFC ($r = 0.73$), ACC ($r = 0.60$; Fig 2B) and precuneus ($r = 0.70$) compared to lean individuals.

4. Discussion

In the current study, adolescents generally exhibited greater activation in regions implicated in visual processing (e.g., middle occipital gyrus), attention (e.g., parietal lobes), cognitive processing (e.g., inferior temporal gyrus, posterior cerebellar lobe), movement (e.g., anterior cerebellar lobe), somatosensory response (postcentral gyrus), and reward (i.e., OFC, ACC) during food commercials relative to non-food commercials and the television show. This pattern of results is consistent with participants' greater recall of food commercials compared to non-food commercials.

Viewing of food commercials versus non-food commercials and the television show was related to greater activation in the occipital gyrus. This finding extends previous evidence that suggest that activation in the occipital gyrus is greater during exposure to food pictures relative to non-food pictures (Schur et al., 2009). Frank and colleagues (Frank et al., 2010) also found that the occipital gyrus displayed greater activation than traditional reward-related regions (e.g., OFC, insula) in response to high-calorie food pictures (compared to non-food pictures that were matched on physical features). Similarly, the occipital gyrus was also the most active brain region during exposure to food logos (relative to control images) in children (Bruce, Bruce, et al., 2012). The lingual gyrus and precuneus were also more active during food commercials relative to other stimuli and these regions (in addition to the occipital lobe) are thought to be related to identifying the salience of appetitive cues (Tang, Fellows, Small, & Dagher, 2012). The lingual gyrus has been found to be more active during food relative to non-food logos (Bruce, Bruce, et al., 2012). Thus, participants in the current study may have found food commercials to be more salient and may have been visually attended more to food commercials relative to the other stimuli in the paradigm. In contrast, television viewing relative to food and non-food commercials was related to greater activation in neural regions associated with semantic processing and language (e.g., superior temporal gyrus, middle frontal gyrus) (Binder et al., 1997; Buchsbaum, Hickok, & Humphries, 2001), which may reflect the more complicated nature of the discussions occurring in the television segments.

The IPL and SPL, which are related to mediating attentional processes (Pessoa, Gutierrez, Bandettini, & Ungerleider, 2002) were more active during food relative to non-food commercials. Greater activation in the SPL has been related to initial orientation to food cues (Yokum, et al., 2012) and greater regional cerebral blood flow in the parietal lobe during exposure to food pictures has been linked to feelings of hunger in obese women (Karhunen, Lappalainen, Vanninen, Kuikka, & Uusitupa, 1997). The ITG was also more active during food relative to non-food commercials and has been linked to a variety of cognitive processes, including semantic memory, language, visual perception, and sensory integration (Noppeney & Price, 2002; Ojemann, Schoenfield-

McNeill, & Corina, 2001; Price, 2002). Both the parietal lobe and temporal gyrus have been found to be more active in healthy children during food logo exposure (Bruce, Bruce, et al., 2012). The cerebellar lobe was also more active during food relative to non-food commercials and the television show, which is consistent with prior research that found greater cerebellar activation in response to food stimuli (Killgore et al., 2003). While the anterior cerebellar lobe has been associated with motor-responses, the posterior cerebellar lobe has been linked to cognitive and attention processes (Stoodley, Valera, & Schmahmann, 2012) and activation in this region may reflect a “hyper-attentive state” (Anderson et al., 2005). Therefore, these findings suggest that participants’ attention may have been more fully captured by the food commercials (relative to the non-food commercials) and greater cognitive processing regarding these commercials may have occurred. This is consistent with participants’ greater recall of food commercials and the association between activation in the posterior cerebellar lobe and food-commercial familiarity.

Somatosensory, motor and reward-related regions were more active during food commercials relative to other stimuli. The postcentral gyrus is implicated in taste perception and food cues exposure is related to activation in this region (Frank, et al., 2010; Killgore, et al., 2003). Increased activation in motor-related regions (i.e., anterior cerebellum, precentral gyrus) (Stoodley, et al., 2012) in response to binge-type food cues for obese binge eaters has been interpreted as reflecting planning to acquire or consume food (Geliebter et al., 2006). The ACC is a region associated with reward-related decision making, motivation and attention (Bush et al., 2002; Tang, et al., 2012; Totah, Jackson, & Moghaddam, 2012). Greater activation in this area is related to high (vs low) calorie food stimuli (Bruce, et al., 2010) and increased response in the ACC to high-calorie food images (relative to control pictures) is predictive of greater difficulty losing weight (Murdaugh, et al., 2012). Activation of the medial OFC is thought to reflect the intensity of desire (Kawabata & Zeki, 2008) and subjective evaluation of reward (Berridge, Ho, Richard, & DiFeliceantonio, 2010). Increased activation in the medial OFC is related to higher ratings of food pleasantness (Kringelbach, 2005) and elevated hunger (Bruce, et al., 2010; Siep et al., 2009), as well as food logo exposure in children (Bruce, Bruce, et al., 2012). The vmPFC is also

thought to encode value (Hare, Camerer, & Rangel, 2009), guide reward-related behaviors (Miller et al., 2007) and is more active during exposure to food (relative to neutral stimuli) (Killgore, et al., 2003). Thus, in the current study, food commercials relative to other stimuli may have triggered increased subjective pleasure and intensified motivation to seek out the featured products.

Contrary to our hypothesis, obese participants exhibited less activation during food commercials relative to non-food commercials in neural regions implicated in visual processing (i.e., cuneus) (Meyer, Baumann, Marchina, & Jancke, 2007) and attention (i.e., posterior cerebellar lobe) (Stoodley, et al., 2012). Obese relative to normal-weight participants also exhibited less activation in regions related to reward (i.e., vmPFC, ACC) (Hare, et al., 2009; Tang, et al., 2012) and salience detection (i.e., precuneus) (Tang, et al., 2012). Although previous research has typically found obese participants to be more responsive to food cues (Bruce, et al., 2010; Martin, et al., 2009; Rothmund, et al., 2007; Stice, et al., 2010; Stoeckel, et al., 2008), a recent study examining neural response to food logos (relative to non-food logos) in children found that healthy weight compared to obese children exhibited greater activation in a number of regions (e.g., frontal gyrus, precuneus, parietal lobe, insula)(Bruce, Lepping, et al., 2012). Thus, branded food items may differ from the type of food cues used in prior studies in a manner that alters the pattern of neural response for lean and obese participants. Prior research also found that obese compared to normal-weight participants exhibited greater activation in multiple brain regions in response to food cues, but only prior to eating a meal (Dimitropoulos, Tkach, Ho, & Kennedy, 2012). Following the meal, obese participants exhibited greater activation in prefrontal and corticolimbic regions relative to normal-weight participants. The obese participants' hypo-activation in pre-meal condition was thought to reflect the use of control strategies to reduce food desire during cue exposure. Obese relative to overweight adolescents in the current study exhibited greater activation in the MTG during food commercials relative to overweight participants. The MTG has been related to the implementation of semantic control used in executively demanding semantic decisions (Whitney, Kirk, O'Sullivan, Ralph, & Jefferies, 2011). In other words, semantic control is associated with focusing on one target response (e.g.,

avoiding the advertised product), when multiple response options are available (e.g., attending to the advertised product). Thus, it is possible that obese participants were using control strategies to reduce their response during food commercials.

Interestingly, overweight participants showed increased activation in the regions associated with attention/cognition (i.e., posterior cerebellum) (Stoodley, et al., 2012) and visual processing (i.e., cuneus) (Meyer, et al., 2007) relative to both obese and lean participants. This pattern of results suggests a non-linear relationship between body weight and neural response to food advertisements. These findings are consistent with the hypothesis that risk for obesity (i.e., being overweight) may be related to hyper-responsivity to food-related reward, but the development of obesity may lead to a reduction in reward circuitry functioning (Stice & Burger, 2012). Consistent with this interpretation, obese relative to overweight participants reported decreased liking of the food commercials.

It is important to consider the limitations of this study. First, the current study was designed to most accurately capture exposure to food commercials in real-world settings. This goal led us to embed commercial breaks in the context of television viewing and to choose commercial stimuli based on the frequency that adolescents were exposed to these commercials types. Thus, the commercials types likely differ in meaningful ways (e.g., color intensity, emotional response). As these variables may differ in certain ways in a manner that increases the effectiveness of marketing for the different product types, we choose not to match commercials on these characteristics. The greater recall of food commercials relative to non-food commercials suggests that food advertising might have been more effective in the current study. It will be important for future research to identify how attributes that differ by commercial type may impact neural response, memory, and eating behavior. Second, the sample size of the current study is relatively small, thus there may have been limited power to detect other effects between weight classes, such as individual differences in the midbrain or striatum. This may be even more likely given the complicated nature of the stimuli used in this paradigm (e.g., commercials). Finally, the current study is cross-sectional, which does not provide information regarding the

time course of eating-related problems and the pattern of neural activation associated with food commercials. It may be especially important to conduct longitudinal studies on this topic, as lean relative to obese participants in the current study exhibited greater activation in the ACC, cuneus, and cerebellum. Greater neural response in these areas during exposure to high-calorie food images (relative to control pictures) is implicated in difficulties with weight loss/maintenance (Murdaugh, et al., 2012). Thus, neural response to food commercials might prospectively predict weight gain, especially in normal-weight adolescents.

5. Conclusions

Despite these limitations, the current study has a number of strengths and implications. This is the first study, to our knowledge, to examine how the brain responds to food commercials. Relative to prior research on food pictures, the stimuli in the current study were designed to evoke desire and prominently featured well-known food brands (e.g., McDonalds) that could also influence neural response (Bruce, Bruce, et al., 2012). Further, the study was designed to recreate the environment that represents how adolescents are often exposed to advertising (e.g., commercials chosen based on age-group exposure and viewed during television commercial breaks). Thus, the study provides some insight into how the ubiquitous nature of food advertising may play a role in the obesity epidemic. Interestingly, regardless of weight class, participants recalled food commercials more than non-food commercials. This is consistent with greater activation across a number of domains (e.g., attention, cognition, reward) in response to food commercials relative to other stimuli. Also, lean relative to obese adolescents exhibited greater neural response to food commercials in regions related to greater difficulty with weight loss/maintenance. This suggests that even adolescents that are not currently exhibiting signs of pathology (e.g., normal-weight) may be impacted by commercials in a manner that might shape future eating tendencies. These findings might inform current policy debates about food advertising to minors.

Table 1. Food and Non-Food Brands Featured in Commercial Breaks²

Food Brands

1. Applebee's Restaurant
2. Cheerios Cereal
3. Chili's Restaurant
4. Denny's Restaurant
5. International House of Pancakes
6. McDonald's Restaurant
7. Olive Garden
8. Subway Restaurant
9. TGI Friday's Restaurant
10. Wendy's Restaurant

Non-Food Brands

1. Acuvue contacts
2. Allstate Insurance
3. AT&T Phone Service
4. Clean&Clear Facial Wash
5. Comcast Cable
6. Ford Car Company
7. H&R Block
8. Listerine Mouthwash
9. T-Mobile Phone Service
10. Verizon Phone Service

² All commercials were 15-seconds in length

Table 2. Pubertal Development, Hunger, and Commercial Ratings of Obese, Overweight, and Lean Participants

	Obese (n = 12)		Overweight (n = 8)		Lean (n = 10)		F (28)	p
	M	SD	M	SD	M	SD		
Pubertal development**	4.63	.50	4.19	.53	4.56	.73	1.44	.26
Hunger	8.8	4.3	10.7	1.9	11.9	5.1	1.58	.22
Top-of-mind recall food commercials	8.2	1.3	8.4	1.5	8.6	1.3	.07	.94
Top-of-mind recall nonfood commercials	7.0	2.9	6.9	1.9	7.3	2.0	.06	.95
Aided recall food commercials	1.8	.4	1.8	.3	1.8	.1	.08	.92
Aided recall nonfood commercials	1.6	.4	1.5	.3	1.6	.3	.17	.85
Liking food commercials	3.26	.43	3.83	.33	3.66	.49	4.57	.03*
Liking nonfood commercials	3.29	.5	3.26	.16	3.13	.19	.40	.67
Familiarity food commercials	4.01	.65	4.27	.92	4.01	.81	.29	.75
Familiarity nonfood commercials	3.66	.81	3.97	1.34	3.59	.98	.29	.76

**Posthoc* analyses identified that obese participants reported liking food commercials significantly less than overweight participants.

** Girls were given line drawings of the 5 stages of breast and female pubic hair development with appropriate written descriptions of each stage. Boys were given line drawings of boys showing the 5 stages of pubic hair and external genitalia development and appropriate written descriptions of each stage. For girls, we averaged the scores on breast and pubic hair development. For boys, we averaged the scores on pubic hair and external genitalia development. The pubertal development scale ranges from *prepubertal* = 1 to *adult stage* = 5.

Table 3. Average Comparisons (N = 30) Contrasting Differences in Brain Responses

to Food Commercials versus Non-food Commercials and Food Commercials versus television show

Contrast and region	BA	<i>k</i>	Z-value	MNI coordinates	Effect size
<i>Food > non-food</i>					
Posterior cerebellar lobe (declive)		813	5.96	-33, -64, -20	>0.90
Middle occipital gyrus			5.09	-30, -88, 7	>0.90
Precentral gyrus	4	78	5.62	57, -19, 37	>0.90
Posterior cerebellar lobe (declive)		382	5.34	30, -52, -20	>0.90
Inferior temporal gyrus			5.29	48, -58, -14	>0.90
Inferior parietal lobe		118	4.81	-42, -40, 52	0.88
Postcentral gyrus	2	4.27	4.19	-45, -28, 46	0.76
Middle occipital gyrus		213	4.79	33, -79, 10	0.87
Precuneus			4.03	24, -79, 34	0.74
Inferior parietal lobe	40	48	4.18	36, -46, 52	0.76
Superior parietal lobe		37	3.71	27, -55, 58	0.68
<i>Food > Television Show</i>					
Cuneus	19	820	5.95	-12, -91, 25	>0.90
Posterior cerebellar lobe (declive)			5.28	-27, -58, -17	>0.90
Anterior cerebellar lobe (culmen)		510	5.69	24, -43, -23	>0.90
Lingual gyrus	18		5.23	21, -79, -14	>0.90
Middle occipital gyrus		227	5.32	36, -79, 13	>0.90
Cingulate gyrus	32	108	4.60	-3, 17, 40	0.84
Middle occipital gyrus		24	4.09	-42, -73, -14	0.75
Ventromedial prefrontal cortex		97	3.90	0, 56, -5	0.71
Anterior cingulate cortex	32		3.82	-6, 47, -2	0.70
Orbitofrontal cortex	11		3.66	3, 50, -11	0.67

For all contrasts, activated regions, Brodmann areas (BA), Z-values, and coordinates within the MNI coordinate system are displayed. Number of contiguous voxels (*k*) are shown for peak coordinates.

Peaks within the regions were considered significant at $k \geq 19$, $p < 0.05$, corrected for multiple comparisons across the entire brain.

Table 4. Group Differences in Brain Activation in Response to Food Commercials versus Non-Food Commercials and Food Commercials versus television show between Obese (n = 12), Overweight (n = 8), and Lean (n = 10) Individuals

Contrast and region	BA	k	Z-value	MNI coordinates	Effect size
<i>Food > non-food</i>					
<u>Obese > overweight</u>					
Middle temporal gyrus		20	4.24	57, -46, -5	0.77
<u>Overweight > obese</u>					
Cuneus	18	47	4.06	-12, -91, 13	0.74
Posterior cerebellar lobe		24	3.86	-21, -76, -26	0.70
<u>Overweight > lean</u>					
Cuneus	18	53	4.02	-15, -88, 16	0.73
Posterior cerebellar lobe		31	4.01	-21, -76, -23	0.73
<i>Food > Television Show</i>					
<u>Obese > overweight</u>					
Middle temporal gyrus		22	4.06	60, -46, -5	0.74
<u>Lean > obese</u>					
Ventromedial prefrontal cortex		21	3.97	-3, 41, -11	0.72
Anterior cingulate cortex			3.31	0, 32, -5	0.60
Precuneus	31	32	3.84	3, -70, 19	0.70

For all contrasts, activated regions, Brodmann areas (BA), Z-values, and coordinates within the MNI coordinate system are displayed. Number of contiguous voxels (*k*) are shown for peak coordinates. Peaks within the regions were considered significant at $k \geq 19$, $p < 0.05$, corrected for multiple comparisons across the entire brain.

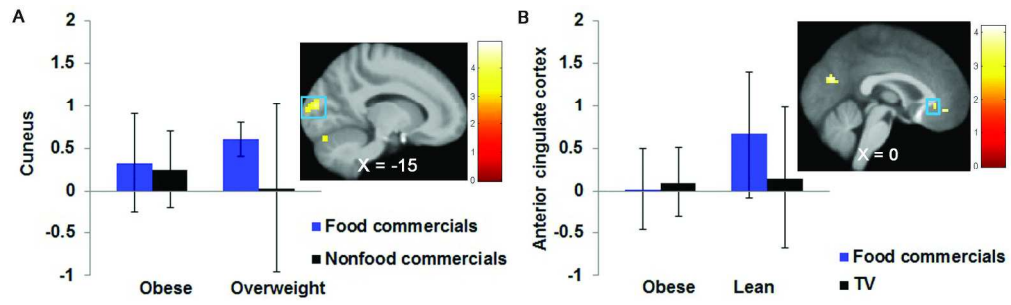

Figure legends

Figure 1. Participants (N = 30) exhibited greater activation in **A**) bilateral posterior cerebellar lobe (MNI: -33, -64, -20, Z = 5.95, k = 811) in response to food commercials versus non-food commercials and greater activation in **B**) the right ventromedial prefrontal cortex (MNI: 0, 56, -5, Z = 3.94, k = 106) in response to food commercials versus television show.

Figure 2. Overweight participants exhibited greater activation in **A**) the left cuneus (MNI: -12, -91, 13, Z = 4.06, k = 47) in response to food commercials versus non-food commercials compared to obese participants. Obese participants exhibited less activation in **B**) the right anterior cingulate cortex (MNI: 0, 32, -5, Z = 3.31) in response to food commercials versus television show compared to lean participants.
